On the Random Clustering with the Conditional Inverse Gaussian-Poisson Distribution

Nobuaki Hoshino*

February 21, 2002

Abstract

We propose the Conditional Inverse Gaussian-Poisson (CIGP) distribution, which is obtained by conditioning the total frequency of an inverse Gaussian-Poisson population model, as a useful distribution of random partitioning of positive integers. Although this type of distribution is important in many fields such as statistical ecology, linguistics and statistical disclosure control, only a few distributions are used owing to the difficulty caused by inevitable combinatorics. We demonstrate the usefulness of the proposed distribution by applying it to some typical data sets. We also give formulae that are necessary for the application of the CIGP distribution.

Keywords: Random Partition, Species abundance, Superpopulation, Disclosure risk

1 Introduction

Scientists observe various kinds of populations. In many instances a population consists of diverse groups (cells, species), and its property is hard to formulate. To comprehend the complex nature of a population, it is often useful to focus upon its heterogeneity. This is a classical theme in statistics, dating back to e.g. Neyman (1939). We shall later discuss more examples, in which the measurement of heterogeneity possesses great importance. Population models have been used for such measurement, and we propose a new population model in the present article.

In Section 1.1, we review the background of statistical population models. In Section 1.2 we introduce the proposed model. Some theoretical results on this model are given in Section 2, and we discuss the parameter estimation of the model in Section 3. Finally Section 4 provides a few applications and concluding remarks.

1.1 A population model

Consider a population of size N consisting of J cells (groups, species) with the size (frequency) $F_j, j = 1, \ldots, J$, $N = \sum_{j=1}^{J} F_j$. Let S_i denote the number of cells of size i. More specifically,

$$S_i = \sum_{j=1}^{J} I(F_j = i), \quad i = 0, 1, \ldots,$$

*Address for correspondence: Nobuaki Hoshino, Faculty of Economics, Kanazawa University, Kakuma-machi, Kanazawa-shi, Ishikawa, Japan. E-mail: hoshino@kenroku.kanazawa-u.ac.jp

where $I(\cdot)$ is the indicator function:

$$I(F_j = i) = \begin{cases} 1, & F_j = i, \\ 0, & F_j \neq i. \end{cases}$$

In literatures, $(S_0, S_1, \ldots)$ are called size indices (Sibuya (1993)), frequencies of frequencies (Good (1965)) or equivalence class (Greenberg and Zayatz (1992)).

Obviously

$$\sum_{i=0}^{\infty} S_i = J, \qquad \sum_{i=1}^{\infty} i \cdot S_i = N.$$

Note that J is the total number of cells including the number of the empty cells S_0. Empty cells may correspond to unseen or extinct species. In the following we denote the number of non-empty cells by

$$U = J - S_0 = \sum_{i=1}^{\infty} S_i.$$

Many authors have regarded F_j's as random variables. Under such an assumption, we can summarize the information of a population with only a few parameters. For example, Fisher et al. (1943) developed the logarithmic series distribution to summarize a population of Malayan butterflies, which commenced the vast studies of statistical ecology or stochastic abundance models. In this situation, a population is composed of J species, and the number of j-th species corresponds to F_j. See Engen (1978) for the context. In addition, there are myriads of examples in linguistics. A writer is deemed to have a vocabulary of J words, and each F_j corresponds to the frequency of the usage of j-th word in the writer's text. The recent book by Baayen (2001) surveys developments of this field to the present.

In these applications, statistical interest lies in the χ^2 test that determines whether one can regard data as being coming from the assumed distribution, since the summary of that kind is meaningless if the assumed distribution does not fit the data. Thus most of researchers have investigated distributions that fit empirically well to data in the sense of χ^2. As a result, their purpose is just fitting to sample data, and there is little interest in the structure of the corresponding population.

However, in some cases the objective of an analysis is to estimate the population structure about size indices. Obviously some ecologists are interested in not samples but a whole population. Let us mention other examples. When a statistical agency disseminates microdata, it is very important to measure the risk of privacy invasion. An individual that is unique in a population is considered to be unsafe to publish. Thus S_1, the number of "population uniques", is a typical index of the risk, and its estimation is necessary unless data are of a census. See Willenborg and de Waal (1996, 2000) for the context of statistical disclosure control. In the domain of linguistics, S_1 is the number of *hapax legomena*, which are the words mentioned once only, and commands special interest. Also we can find a similar problem in database merging. When databases have common individuals, it is necessary to identify how many individuals are in common. Since a database is often composed of numerous records, it is valuable to estimate such overlaps based on samples.

As regards the estimation of size indices, it is useful to assume a random population model, even though the objective is not to summarize information. Let us assume simple random sampling without replacement; if there is no assumption about a finite population, the unique

unbiased estimator of S_i is useless because of its large variance. See Section 2.3 of Engen (1978). The author would rather adopt the superpopulation model approach or the empirical Bayes method. Namely the estimator of a size index is its expectation under the estimated superpopulation model. For example, Bethlehem et al. (1990) regarded F_j's as gamma-Poisson mixture, which has two parameters; the parameters were estimated from data, whence they calculated $\mathrm{E}(S_1)$ as an index of the risk.

The present article assumes the superpopulation approach to estimate population size indices. As we have mentioned, not much attention has been paid to the relationship between samples and the population. Our approach explicitly considers the relationship, however. The sample size is denoted by n; the sample size indices are similarly defined and denoted by $(s_0, s_1, \ldots)$. We denote the number of non-empty cells by

$$u = \sum_{i \geq 1} s_i .$$

Assuming a population model, we can derive the sampling distribution of $(s_0, s_1, \ldots)$. We then construct estimators of the parameters of the population model. The estimator of S_i is its expectation given the estimates of parameters. Note that $\mathrm{E}(S_i)$ depends on the population size $N = \sum_j F_j$.

In many cases, including Bethlehem et al. (1990), F_j's are regarded as independently identically distributed Poisson mixture. Then the population size N is a random variable, and this fact may be a problem because concerning the estimation of size indices the population size is given and fixed in practice. To ease this conflict, one may assume $\mathrm{E}(N) = N_0$ as in Bethlehem et al. (1990), where the number of parameters was reduced to one. Under the restriction, we can immediately obtain the sampling distribution with Bernoulli sampling (Särndal et al. (1992)), in which each individual is independently sampled with success probability n_0/N_0. Namely, the sampling distribution is the result of substituting the observed number of samples n_0 for N_0 in the distribution of a population. Such treatment is thus expedient.

However, simple random sampling without replacement requires the population size N to be fixed at N_0. Hence population models where $N = N_0$ are more realistic in cases such as statistical disclosure control, where simple random sampling without replacement is employed. Although Bernoulli sampling may be valid as an approximation of simple random sampling without replacement, we need to investigate models in which $N = N_0$ is fixed.

The difficulty of a model where its population size is fixed is that it involves combinatorics. In fact it is equivalent to random partitioning of the positive integers, which is itself an interesting subject of probability; see Hoshino (2001) for an application of a formula of this field. Although we can utilize existing results, only a few models seem to be treatable. Hence there is great need to develop useful models that satisfy the size restriction, in order to handle various populations.

Among known models, the Dirichlet-multinomial model is obtained by conditioning the gamma-Poisson model as $N = N_0$ (Takemura (1999)). Similarly, if we can easily derive the distribution of N under independently identically distributed F_j's, the construction of a size-restricted model may be straightforward. Holla (1966) introduced inverse Gaussian-Poisson mixture, which is closed under convolution; the present article investigates the conditional population model of inverse Gaussian-Poisson mixture.

The inverse Gaussian-Poisson mixture is a special case of the generalized inverse Gaussian-Poisson mixture proposed by Sichel (1971), which is, however, less treatable than the inverse

Gaussian-Poisson mixture. See Jørgensen (1982) for the generalized inverse Gaussian distribution. With regard to the (generalized) inverse Gaussian-Poisson mixture, there are a certain number of applications in statistical ecology and linguistics. Here we only mention Sichel (1997) as an example, though his population model is different from ours. Seshadri (1999) provides an excellent review on the inverse Gaussian distribution; its Section 7.1 is devoted to the inverse Gaussian-Poisson mixture. Since the inverse Gaussian-Poisson mixture has been used to describe populations, our approach seems to be promising for various applications.

1.2 The derivation of the Conditional Inverse Gaussian-Poisson distribution

The inverse Gaussian distribution is defined as

$$\mathrm{P}_{IG}(\lambda;\alpha,\theta)=\frac{(2\sqrt{1-\theta}/(\alpha\theta))^{\frac{-1}{2}}}{2K_{-1/2}(\alpha\sqrt{1-\theta})}\lambda^{-\frac{3}{2}}\exp(-(\frac{1}{\theta}-1)\lambda-\frac{\alpha^2\theta}{4\lambda}),\quad \lambda>0, \tag{1}$$

for $0<\theta<1, \alpha>0$, where

$$K_{-1/2}(\xi)=\sqrt{\frac{\pi}{2}}\xi^{-1/2}\exp(-\xi) \tag{2}$$

is the modified Bessel function of the third kind of order $-1/2$.

Suppose that a random variable Y is distributed as Poisson with mean λ, and let λ distribute with its density (1). Then the distribution of Y is widely known to be

$$\mathrm{P}_{IGP}(Y=y;\alpha,\theta)=\sqrt{\frac{2\alpha}{\pi}}\exp(\alpha\sqrt{1-\theta})\frac{(\alpha\theta/2)^y}{y!}K_{y-1/2}(\alpha),\quad y=0,1,2,\ldots. \tag{3}$$

See Chapter 7.1 of Seshadri (1999) for more detail. In the present article, we refer to (3) as the inverse Gaussian-Poisson distribution and denote it by $IGP(\alpha,\theta)$.

We can obtain

$$K_{y-1/2}(\alpha)=\sqrt{\frac{\pi}{2\alpha}}\exp(-\alpha)(\sum_{i=0}^{y-1}\frac{(y-1+i)!}{(y-1-i)!i!}(2\alpha)^{-i}),\quad y=1,2,\ldots,$$

from (2) and the fact that $K_{-1/2}(\xi)=K_{1/2}(\xi)$, by means of

$$K_{\gamma+1}(\alpha)=\frac{2\gamma}{\alpha}K_{\gamma}(\alpha)+K_{\gamma-1}(\alpha).$$

In addition, Ismail (1977) showed that

$$K_{\gamma}(\alpha)\approx 2^{\gamma}\gamma^{\gamma}\exp(-\gamma)\alpha^{-\gamma}\sqrt{\frac{\pi}{2\gamma}} \tag{4}$$

when γ is large. Equation (4) is useful since the computation of the modified Bessel function of the third kind may overflow as $\gamma\to\infty$. Consequently, computation on the inverse Gaussian-Poisson distribution is not very hard. Consult Watson (1944) for the results on Bessel functions.

Henceforth we consider the population model that was discussed in Section 1.1, under the assumption that $F_j, j=1,\ldots,J$, are independently identically distributed as $IGP(\alpha,\theta)$. Namely, we suppose that

$$\mathrm{P}(F_1,\ldots,F_J)=\prod_{j=1}^{J}\sqrt{\frac{2\alpha}{\pi}}\exp(\alpha\sqrt{1-\theta})\frac{(\alpha\theta/2)^{F_j}}{F_j!}K_{F_j-1/2}(\alpha),$$

or

$$\mathrm{P}(S_0, S_1, \ldots) = J! \prod_{i=0}^{\infty} \{\sqrt{\frac{2\alpha}{\pi}} \exp(\alpha\sqrt{1-\theta}) \frac{(\alpha\theta/2)^i}{i!} K_{i-1/2}(\alpha)\}^{S_i} \frac{1}{S_i!}. \tag{5}$$

One merit of the IGP model (5) is that we can evaluate the exact distribution of the population size N. The probability generating function of (3) was shown to be

$$G(z) = \exp(\alpha(\sqrt{1-\theta} - \sqrt{1-z\theta})) \tag{6}$$

by Sankaran (1968). Hence we can see that the sum of J random variables that are independently identically distributed as $IGP(\alpha, \theta)$ is distributed as $IGP(J\alpha, \theta)$. That is,

$$\mathrm{P}(N) = \sqrt{\frac{2J\alpha}{\pi}} \exp(J\alpha\sqrt{1-\theta}) \frac{(J\alpha\theta/2)^N}{N!} K_{N-1/2}(J\alpha). \tag{7}$$

We are interested in the conditional population model given its population size N; the model (5) divided by (7) becomes

$$\begin{aligned} \mathrm{P}(S_0, \ldots, S_N | N) &= \frac{J! \prod_{i=0}^{N} \{\sqrt{\frac{2\alpha}{\pi}} \exp(\alpha\sqrt{1-\theta}) \frac{(\alpha\theta/2)^i}{i!} K_{i-1/2}(\alpha)\}^{S_i} \frac{1}{S_i!}}{\sqrt{\frac{2J\alpha}{\pi}} \exp(J\alpha\sqrt{1-\theta}) \frac{(J\alpha\theta/2)^N}{N!} K_{N-1/2}(J\alpha)} \\ &= (\frac{2\alpha}{\pi})^{\frac{J-1}{2}} \frac{J!N!}{J^{N+1/2} K_{N-1/2}(J\alpha)} \prod_{i=0}^{N} \{\frac{K_{i-1/2}(\alpha)}{i!}\}^{S_i} \frac{1}{S_i!}. \end{aligned} \tag{8}$$

The right hand side of (8) seems to be a new distribution with one parameter; it is worthy of note that (8) is derived from the distribution with two parameters. We refer to (8) as the Conditional Inverse Gaussian-Poisson distribution ($CIGP(\alpha)$).

2 On the property of $CIGP(\alpha)$

In this section we will clarify a few properties of $CIGP(\alpha)$ that are important in applications. To make the dependence of $CIGP(\alpha)$ on J explicit, we denote the right hand side of (8) by

$$\mathrm{P}_J(S_0, \ldots, S_N) = (\frac{2\alpha}{\pi})^{\frac{J-1}{2}} \frac{J!N!}{J^{N+1/2} K_{N-1/2}(J\alpha)} \prod_{i=0}^{N} \{\frac{K_{i-1/2}(\alpha)}{i!}\}^{S_i} \frac{1}{S_i!}. \tag{9}$$

Note that $\alpha > 0$.

First we see relationships among distributions connected with the CIGP model. When we assume $\theta = 1$, the density of inverse Gaussian (1) equals the density of the reciprocal gamma distribution (Pearson type 5, or inverted gamma). Since the derivation of $CIGP(\alpha)$ does not depend on the value of θ, the conditional model of reciprocal gamma-Poisson mixture given N is $CIGP(\alpha)$. Takemura (1999) clarified that the conditional model of gamma-Poisson mixture (=negative binomial) given N equals Dirichlet-multinomial mixture, which is a multivariate generalization of beta-binomial mixture. Therefore, in a sense, the CIGP model corresponds to Dirichlet-multinomial mixture. See Hoshino and Takemura (1998) for more detailed discussion on distributions relating to gamma-Poisson mixture.

We then show the expectations of size indices.

Theorem 1 *Suppose that size indices are distributed as* (9). *Then the factorial moments are*

$$\mathrm{E}\,(\prod_{j=1}^{N} S_j^{(r_j)}) = (\frac{2\alpha}{\pi})^{\frac{r}{2}} \frac{N!J!K_{N-R-1/2}((J-r)\alpha)(J-r)^{N-R+1/2}}{(N-R)!(J-r)!J^{N+1/2}K_{N-1/2}(J\alpha)} \prod_{j=1}^{N} (\frac{K_{j-1/2}(\alpha)}{j!})^{r_j},$$

where $r = \sum_{j=1}^{N} r_j$, $R = \sum_{j=1}^{N} j r_j$, *and* $S_j^{(r_j)} = S_j(S_j-1)\cdots(S_j-r_j+1)$.

Proof For simplicity, here we evaluate $E(S_j)$. Let us write

$$\mathcal{S}(N) = \{\boldsymbol{S} = (S_1, \ldots, S_N) | \sum_{i \geq 1} i S_i = N\}.$$

Then for $S_j \geq 1$, $j = 1, 2, \ldots$, we have

$$\begin{aligned} S_j\, \mathrm{P}_J(S_0, \ldots, S_N|N) &= \mathrm{P}_{J-1}(S_0, \ldots, S_{j-1}, S_j - 1, S_{j+1}, \ldots, S_N|N-j) \\ &\quad \times \sqrt{\frac{2\alpha}{\pi}} (\frac{K_{j-1/2}(\alpha)}{j!}) \frac{N!K_{N-j-1/2}((J-1)\alpha)(J-1)^{N-j+1/2}}{(N-j)!J^{N-1/2}K_{N-1/2}(J\alpha)}. \end{aligned}$$

Note that $S_j\, \mathrm{P}_J(S_0, \ldots, S_N|N) = 0$ if $S_j = 0$. Thus

$$\begin{aligned} \mathrm{E}_J(S_j|N) &= \sum_{\boldsymbol{S} \in \mathcal{S}(N)} S_j\, \mathrm{P}_J(S_0, \ldots, S_N|N) \\ &= \sqrt{\frac{2\alpha}{\pi}} (\frac{K_{j-1/2}(\alpha)}{j!}) \frac{N!K_{N-j-1/2}((J-1)\alpha)(J-1)^{N-j+1/2}}{(N-j)!J^{N-1/2}K_{N-1/2}(J\alpha)} \\ &\quad \times \sum_{\boldsymbol{S} \in \mathcal{S}(N)} \mathrm{P}_{J-1}(S_0, \ldots, S_{j-1}, S_j - 1, S_{j+1}, \ldots, S_N|N-j)\, I(S_j \geq 1). \end{aligned} \quad (10)$$

Since

$$\begin{aligned} &\sum_{\boldsymbol{S} \in \mathcal{S}(N)} \mathrm{P}_{J-1}(S_0, \ldots, S_{j-1}, S_j - 1, S_{j+1}, \ldots, S_N|N-j)\, I(S_j \geq 1) \\ &= \sum_{\boldsymbol{S} \in \mathcal{S}(N-j)} \mathrm{P}_{J-1}(S_0, \ldots, S_{N-j}|N-j) = 1, \end{aligned}$$

we obtain

$$\mathrm{E}_J(S_j|N) = \sqrt{\frac{2\alpha}{\pi}} (\frac{K_{j-1/2}(\alpha)}{j!}) \frac{N!K_{N-j-1/2}((J-1)\alpha)(J-1)^{N-j+1/2}}{(N-j)!J^{N-1/2}K_{N-1/2}(J\alpha)} \quad (11)$$

from (10). We have only evaluated $E(S_j)$, but $\mathrm{E}\,(\prod_{j=1}^{N} S_j^{(r_j)})$ can be evaluated by the same argument. Q.E.D.

Figure 1 plots the expectations of size indices with parameter values $\alpha = 0.1, 0.5, 1, 10, 50$ under $N = 1000$ and $J = 10000$. The vertical axis shows $\mathrm{E}(S_j)$, and the horizontal axis corresponds to $j = 1, 2, \ldots, 5$. We can observe that the expectation of a size index is decreasing with respect to the size; this is the pattern that we frequently find in applications. The difference

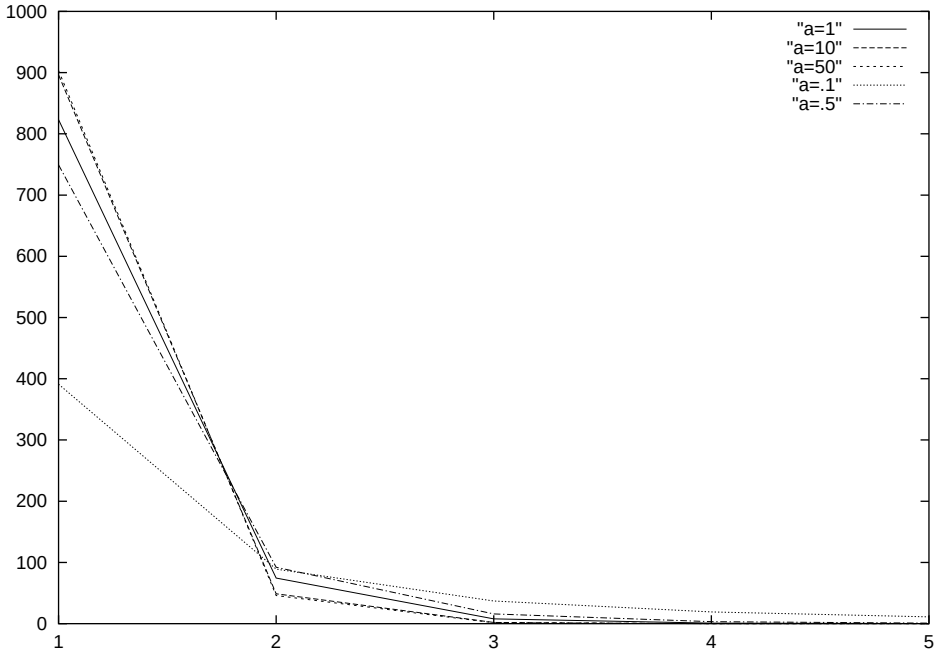

Figure 1: *The expectations of size indices with various parameter values of* α $(N = 1000,\ J = 10000)$

between the size indices of $\alpha = 10$ and $\alpha = 50$ appears very small compared to the difference between the values of $\alpha = 0.1$ and $\alpha = 0.5$.

We now discuss the sampling distribution of $CIGP(\alpha)$. Since the CIGP model does not depend on the label of each individual, Lemma 1 of Takemura (1999) assures that we can immediately derive the sampling distribution as a result of substituting n for N of the population distribution. In other words, the distribution of n samples directly drawn from the infinite population ($CIGP(\alpha)$) is the same as that of n samples drawn from the finite population of size N, which is in turn drawn from the infinite population.

Theorem 2 *Suppose that the distribution of population size indices is* (9) *and n samples are drawn with simple random sampling without replacement. Then the sample size indices are distributed according to*

$$P_J(s_0, \ldots, s_n) = (\frac{2\alpha}{\pi})^{\frac{J-1}{2}} \frac{J!n!}{J^{n+1/2} K_{n-1/2}(J\alpha)} \prod_{i=0}^{n} \{\frac{K_{i-1/2}(\alpha)}{i!}\}^{s_i} \frac{1}{s_i!}. \tag{12}$$

3 Parameter estimation

This section treats the estimation of α from samples that are distributed according to $CIGP(\alpha)$. We provide the maximum likelihood estimator and two approximate estimators.

3.1 Maximum Likelihood (ML) estimation

We will denote the log likelihood of (12) by

$$L = \frac{J-1}{2} \log(2\alpha) - \log K_{n-1/2}(J\alpha) + \sum_{i=0}^{n} s_i \log K_{i-1/2}(\alpha) + Const.$$

In the following we will use this notation:

$$R_\gamma(\alpha) = \frac{K_{\gamma+1}(\alpha)}{K_\gamma(\alpha)},$$

and it is widely known that

$$\frac{\partial \log K_\gamma(\alpha)}{\partial \alpha} = -R_\gamma(\alpha) + \frac{\gamma}{\alpha}. \tag{13}$$

See Seshadri (1999, p.125) for instance.

Now we construct the ML estimator: the solution of $dL/d\alpha = 0$. Equation (13) leads to the following expression of the derivative of L:

$$\begin{aligned} \frac{dL}{d\alpha} &= \frac{J-1}{2\alpha} - \{-R_{n-1/2}(J\alpha) + \frac{n-1/2}{J\alpha}\}J + \sum_{i=0} s_i \{-R_{i-1/2}(\alpha) + \frac{i-1/2}{\alpha}\} \\ &= JR_{n-1/2}(J\alpha) - \sum_{i=0}^{n} s_i R_{i-1/2}(\alpha), \end{aligned}$$

by

$$\sum_{i=0}^{n} s_i = J \quad \text{and} \quad \sum_{i=0}^{n} i s_i = n.$$

The ML estimate obviously requires numerical evaluation; we can adopt the Newton-Raphson method using the second derivative:

$$\frac{d^2L}{d\alpha^2} = J^2\{R^2_{n-1/2}(J\alpha) + \frac{2n}{J\alpha}R_{n-1/2}(J\alpha)\} - \sum_{i=0} s_i\{R^2_{i-1/2}(\alpha) + \frac{2i}{\alpha}R_{i-1/2}(\alpha)\} - J^2 + J.$$

Note that

$$\frac{\partial R_{\gamma-1/2}(\alpha)}{\partial\alpha} = R^2_{\gamma-1/2}(\alpha) - \frac{2\gamma}{\alpha}R_{\gamma-1/2}(\alpha) - 1.$$

The estimators that are discussed in Section 3.2 can be used for the starting value of α in such an iterative procedure.

3.2 Approximate estimation

The expectation of a sample size index is derived from substituting n for N in (11). Therefore we may be able to apply the method of moments. However, what is inconvenient is the evaluation of polynomials of order n (i.e. $K_{n-1/2}$). Here we utilize estimators of the IGP distribution to construct an approximate moment estimator of the CIGP parameter, since it is easy to calculate. We also introduce another approximate estimator, which is a function of s_0.

If Y is a random variable that is subject to $IGP(\alpha, \theta)$, equation (6) implies that

$$\mathrm{E}(Y) = \frac{\alpha\theta}{2\sqrt{1-\theta}},$$

and

$$\mathrm{V}(Y) = \frac{\alpha\theta(2-\theta)}{4(1-\theta)^{\frac{3}{2}}}.$$

We substitute the sample average n/J for $\mathrm{E}(Y)$ and the sample variance

$$v = \frac{\sum_{i=0}^{n}(i - n/J)^2 s_i}{J}$$

for $\mathrm{V}(Y)$. The solution of these simultaneous equations is given by

$$\theta = \frac{2n - 2Jv}{n - 2Jv}, \quad \text{and} \quad \alpha = \frac{2n\sqrt{1-\theta}}{J\theta}.$$

We propose using above equation about α as our approximate estimator:

$$\tilde{\alpha} = \frac{n\sqrt{n(2Jv - n)}}{J(Jv - n)}. \tag{14}$$

Although (14) is simple enough, it may not be efficient enough. On the IGP distribution, Sichel (1982) calculated asymptotic efficiencies for the joint estimation of α and θ for the method of moments. According to his result, the method of moments is inefficient at α being as great as 10 when $\theta = 0.97$, which is claimed to be a typical case of parameter values. Sichel (1973) proposed another estimator of the IGP parameter α, whose efficiency was high for small α in the Sichel (1982)'s experiment. It leads to

$$\bar{\alpha} = -\frac{1}{2}(\log s_0 - \log J)(1 + \frac{n/J}{n/J + \log s_0 - \log J}) \tag{15}$$

in our setting. See Section 4 for an empirical comparison of these estimators.

4 Application results and conclusions

In this section we examine the applicability of the CIGP model to real data. We fit the CIGP model to plankton data (Table 1), lice data (Table 2) and Japanese labor force survey data (Table 3). The present article then concludes with some remarks.

Barnes and Marshall (1951) provided plankton data series; Reid (1981) fitted Log-Normal-Poisson mixture (LNP, 2 parameters), Gamma-Poisson mixture (GP, 2 parameters) and the Neyman type A (NY, 2 parameters) distribution to a data set of $n = 232$ and $J = 120$ from the series. In these models, the total frequency is not fixed. Namely, n is the sum of independently identically distributed random variables. Now we apply $CIGP(\alpha)$ to the same data set; the results are shown in Table 1. Concerning the CIGP model, the ML estimate appears to be $\hat{\alpha} = 10.35$ in this case, and the fitted values of size indices are the expectations under $\hat{\alpha}$. The approximate moment estimate by (14) is $\tilde{\alpha} = 4.49$, and another estimate by (15) is $\bar{\alpha} = 6.50$; these estimates are not very close to the ML estimate. We observe that the fits of the models are satisfactory in terms of the χ^2 criterion. If n is regarded as known, it is reasonable to include the information of the sample size in a model, whereby the degree of freedom increases without great loss of fit as the case of the CIGP model.

Next we compare the CIGP model with the IGP model (3). Stein et al. (1987) fitted the IGP distribution to lice data (William (1964)) with $n = 7442, J = 1083$. We apply the CIGP model to the same data; see Table 2 for the results. These fits are not good, yet similar. We also observe that ML estimates $\hat{\alpha}_{IGP} = 0.645$ and $\hat{\alpha}_{CIGP} = 0.644$ are similar. According to Sichel (1982), α_{IGP} describes the shape of the distribution, whereas θ_{IGP} controls the upper tail. This claim seems to explain the similarity between $\hat{\alpha}_{IGP}$ and $\hat{\alpha}_{CIGP}$. The approximate moment estimate is $\tilde{\alpha} = 1.069$, and another estimate is $\bar{\alpha} = 0.579$ here.

Sichel (1982) evaluated the asymptotic covariance matrix of $\hat{\alpha}_{IGP}$ and $\hat{\theta}_{IGP}$. He remarked that the correlation between $\hat{\alpha}_{IGP}$ and $\hat{\theta}_{IGP}$ is negative, and is generally substantial in the useful range of values. Hence Stein et al. (1987) proposed a reparameterization to avoid numerical instability. However, as far as the CIGP model is concerned, n seems to determine the tail, which is governed by θ in the IGP model. We can thus regard the CIGP model as one way to overcome aforementioned numerical instability without the arbitrariness of a reparameterization.

We now demonstrate the applicability of the CIGP model to the estimation of population size indices in the field of statistical disclosure control. This is interesting because there seems to exist no application of the IGP distribution in this field. Sai and Takemura (2000) calculated the size indices of Japanese labor force survey data that were collected in December 1997. We apply the CIGP model to one of their anonymized data sets; our interest lies in the number of population uniques (S_1) with respect to the degree of the anonymization. Each record contains the information of variables such as sex or age; these variables are classified in some categories, with the result that J is the product of the number of categories in the variables. In this case, $J = 5.644 \times 10^{12}$ and $n = 908$. Observe Table 3 for the result of fitting. The ML estimate $\hat{\alpha}$ is 9.047×10^{-10}; $\tilde{\alpha} = 7.423 \times 10^{-10}$ and $\bar{\alpha} = 9.061 \times 10^{-10}$. The numbers of nonzero-frequency groups (u) are the same between the observed set and the fitted set.

Under the superpopulation approach, the estimator of S_1 is $\mathrm{E}(S_1|N)$ of the CIGP distribution, where N equals 1.028 million. However, the author could not compute the value within a reasonable time. Here we only give an approximate value $E(S_1) \approx 2553$; this value can be obtained with the following proposition, which is an immediate consequence of (4) and (11).

i	s_i	LNP	GP	NY	CIGP
0	23	23.3	21.0	21.4	20.6

Table 1: *Frequency distribution of Oithona similis nauplii (Barnes and Marshall, 1951)*

Proposition 1 *Suppose that size indices are distributed according to (9). Then, as* $N \to \infty$,

$$\mathrm{E}(S_1|N) \approx \exp(1-\alpha)\frac{N\alpha(J-1)}{2}\frac{(N-3/2)^{N-2}}{(N-1/2)^{N-1}}.$$

We now conclude the discussion with some remarks. The CIGP model can surely be used in the estimation of population size indices, and it has merits particularly in being free from the numerical instability that is reported on the ML estimation of the IGP parameters. The estimate by (15) tends to be closer to the ML estimate in our experiments, which suggests that $\bar{\alpha}$ may be better than $\tilde{\alpha}$ on real data. According to Takemura (1999), we can derive the Ewens distribution (See Chap. 41 of Johnson et al. (1997)) from Dirichlet-multinomial mixture by a limiting argument. The same kind of limiting distribution of the CIGP model, where $J\alpha$ is fixed and $\alpha \to 0$, will be discussed in the author's subsequent paper. The CIGP model needs the information of s_0, but many data in applications have no information of s_0. In such a case, we may be able to use that limiting distribution.

Acknowledgements

This manuscript is written during the author's visit to Carnegie Mellon University, which is financed by the Japanese ministry of education, culture, sports, science and technology. The author would like to express sincere thanks for their support and Prof. Takemura's useful comments on the subject.
